9 Abstract

Moffatt et al. (2020) reported the results of an experiment (N = 26 in the final sample) 10 comparing the facial (surface) electromyographic correlates of mental rumination and 11 distraction, following an experimentally induced stressor. Based on the absence of 12 significant difference in the perioral muscular activity between the rumination and distraction conditions, Moffatt et al. (2020) concluded that self-reported inner experience was unrelated to peripheral muscular activity as assessed using surface electromyography. 15 We suggest this conclusion is hasty and based on waggly evidence. Indeed, concluding on 16 the absence of an effect based on a low-powered non-significant p-value is strongly 17 problematic/uninformative. Moreover, the relation between self-reports and physiological 18 measures was not directly assessed, but only indirectly inferred from differences (or absence 19 thereof) in group means. Given the ample inter-individual variability in these measures (as 20 suggested by our reanalysis), we think inferring the individual-level relation between 21 self-reports and physiological measures from group means is inappropriate. Given these 22 limitations, we conclude that it is unclear whether the target article adds to the 23 current/extent knowledge and we suggest ways forward, both from a theoretical and from a methodological perspective. Complete source code, reproducible analyses, and figures are 25 available at https://github.com/lnalborczyk/inner experience EMG.

Introduction

The activity of silently talking to oneself or "inner speech" is a foundational ability...

despite its multiple adaptive functions in everyday life, inner speech can go awry and leads

to sustained negative... These inner speech "dysfunctions" (for reviews, see Alderson-Day &

Fernyhough, 2015; Lœvenbruck et al., 2018; Perrone-Bertolotti et al., 2014)...

Given the predominantly verbal nature of rumination [], we previously proposed to study rumination as other forms of inner speech have been studied in the past, namely using surface electromyography and motor interference protocols (e.g., Nalborczyk et al., 2017; Nalborczyk, 2019; Nalborczyk, Perrone-Bertolotti, et al., 2020; Nalborczyk, Grandchamp, et al., 2020)...

We have previously shown that... However, it was unclear... therefore, the extension of our study by Moffatt et al. (2020), which consisted by including a distraction control group, is more than welcome... However...

The main conclusion from Moffatt et al. (2020) is that inner experience between induced rumination and distraction differs "without a change in electromyographic correlates of inner speech". In other words, their conclusion is that inner experience is unrelated (or loosely related) to the electromyographic correlates of inner speech, which are thought to be represented mostly by the EMG amplitude recorded over the OOI and OOS muscles. However, for this in-sample observation to be of interest in an out-of-sample context (i.e., to be informative of other non-observed individuals, or said otherwise, to bring information about the population), this absence of difference has to be based on sufficiently powered sample size (given the target effect size) as well as on reliable measures. Moreover, a simple visual exploration of the data reveals important variability between individuals in the main effect of interest. That is, some participants had higher perioral (OOS and OOI) muscular activity in the rumination condition than in the distraction

- condition, and some other participants showed the reverse pattern. This suggests
 unexplored variation in the determinants of this effects (e.g., the content of the inner
 experience). Indeed, the relation between the inner experience and the physiological
 correlates of inner speech production was only inferred from group means. However, given
 the previous point, this appears highly problematic. We explore each of these limitations
- 62 and suggests ways forward in the following section.

Exploring the data

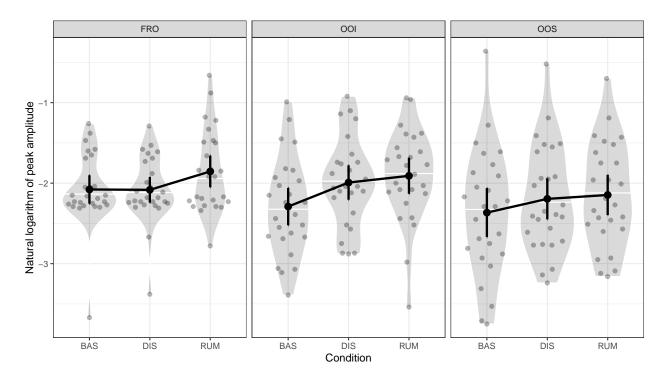

Figure 1. Average log-EMG amplitude by muscle and condition. The black dots and intervals represent the by-group average and 95% confidence interval (N=26). The horizontal white line in the violin plot represents the median. The grey dots represent the individual-level average natural logarithm of the EMG amplitude by muscle and condition.

Posterior distribution of the difference between the distraction and rumination

66 conditions...

67 Concluding on the null from low-powered studies is uninformative

There is an infamous tradition of running uninformative null-hypothesis significance tests in Psychology (e.g., Meehl, 1997, 1978, 1990a, 1990b, 1967). By "uninformative", we mean that some null-hypothesis significance tests are often *not* diagnostic with regards to the substantive question of interest...

As highlighted by many authors (e.g., Pollard & Richardson, 1987; Rouder et al.,
2016), concluding on an absence of difference based on not obtaining evidence for the
difference is the continuous extension of the logical fallacy of the... The argument from
ignorance, such as "Science has found no proof of intelligent life nearby us in space,
therefore intelligent life does not exist nearby us in space."... the absence of evidence fallacy
or fallacy of acceptance...

This problem is tackled in modern usages of null-hypothesis significance test by ensuring that the test has good severity (e.g., Mayo & Spanos, 2006; Mayo, 2018). In general terms, we have evidence for a claim to the extent that it survives a stringent scrutiny, that is if it survives severe tests. In other words, some claim (e.g., $\theta = 0$) is said to be severely tested) if it had great chances of being falsified, was the claim false. More formally, we can define SEV(T, x0, H), the severity with which claim H passes test T with outcome x0, and SEV $(\mu > \mu_1) = \Pr(d(X) \le d(x0); \mu = \mu_1)$ (Mayo, 2018; Mayo & Spanos, 2006)...To put it simply... https://www.analytics-toolkit.com/glossary/severity/...

Anticipating the critics on the power of their study (a critic that was probably raised during peer review), Moffatt et al. (2020) report the results of a (possibly ran a posteriori) power analysis using the effect size reported in Nalborczyk et al. (2017) of d = 0.72, which is highly optimistic estimate of the substantive effect of interest in the target article (i.e.,

- ₉₀ the difference in EMG amplitude between the rumination and distraction conditions) as
- this effects represents the standardised mean difference between a rest period and a
- ⁹² rumination one (Nalborczyk et al., 2017)...

```
# How many participants do we need for a target statistical power of 0.8?
library(pwr)
pwr.t.test(
  d = 0.72, sig.level = 0.05, power = 0.8,
  type = "one.sample", alternative = "two.sided"
  )
```

```
##
            One-sample t test power calculation
   ##
   ##
95
                      n = 17.16004
   ##
96
                      d = 0.72
   ##
97
             sig.level = 0.05
   ##
   ##
                 power = 0.8
   ##
           alternative = two.sided
100
```

We suggest the (a priori) power of the study ran by Moffatt et al. (2020) was much 101 lower than suggested by the authors. Indeed, we may speculate that the effect (i.e., the 102 standardised mean difference in EMG amplitude) between the rumination and distraction 103 conditions may be much weaker than the effect (i.e., the standardised mean difference in EMG amplitude) between the rumination and the rest conditions. If we assume that the former is half the size of the latter (which seems reasonable given the high inter-individual 106 variability in such effects, cf. the next section but also Nalborczyk, Grandchamp, et al., 107 2020), therefore the a priori power of the main statistical test from Moffatt et al. (2020) 108 was around 0.44, meaning that they had less than 1 chance out of 2 to find a significant 109

effect, given that the effect in the population was actually 0.36. Because this is less than
the chance of obtaining a head in a coin flip, we feel these resources may have been better
invested.

```
# A priori power for n = 26 (per condition) and d = 0.36

pwr.t.test(
  n = 26, d = 0.72 / 2, sig.level = 0.05,
  type = "one.sample", alternative = "two.sided"
  )

Anticipating the legitimate critique that the absence of a significant difference is not necessarily "significant" evidence for the absence of an effect, Moffatt et al. (2020) reported the following Bayes factor (BF) analysis:

"[...] therefore it is possible that the sample size of the present study lacked sufficient power to detect the effect of rumination on muscle activity. In order to test this, a Bayesian paired samples t-test was conducted for the peak log values of muscle activity between the rumination and distraction conditions.

This revealed strong evidence in favour of the alternative hypothesis for the FRO muscle ($B_{10} = 18.79$), and moderate evidence in favour of the null

hypothesis for the OOS $(B_{10}=0.232)$ and OOI $(B_{10}=0.278)$ muscles, according to current guidelines for interpreting Bayes factors [43]."

While we appreciate the effort, the current approach poses new problems. First,
contrary to what the authors suggest, computing a BF (i.e., comparing two models) does
not solve at all the problem of low power...

We first fitted a multivariate Bayesian regression model with varying-intercepts (by participant) and weakly informative priors on these data using the brms package (Bürkner, 2017). From there, we i) generated new datasets from the posterior predictive distribution and ii) we computed the BF in favour of the alternative hypothesis (BF₁₀) using the BayesFactor package (Morey & Rouder, 2018). We used a "medium" prior (i.e., a scale of 1) on the scale of the Cauchy prior for the alternative hypothesis. We repeated this procedure for varying sample sizes from 20 to 200 participants (by increments of 10 participants) with 1000 simulations (i.e., 1000 simulated datasets) for each sample size.

As shown in Figure 2, the natural logarithm of the BF in favour of the alternative hypothesis is growing proportionally with the sample size. More precisely, whereas low sample sizes (i.e., below 80) support the null hypothesis, adequately-powered sample sizes support the alternative hypothesis for all three facial muscles for sample sizes larger than 80 participants. For instance, the average BF₁₀ computed for the OOI muscle with a sample size of 160 participants is of $\exp(2.18) \approx 8.85$, indicating that these data are approximately 8.85 times more likely under the alternative hypothesis than under the null hypothesis.¹

We should keep in mind some limitations of this analysis, which uses simulated datasets form the posterior predictive distribution estimated on the data collected by Moffatt et al. (2020). This analysis is the loose Bayesian analogue of the frequentist post-hoc power analysis, which has been much criticised (e.g., Lakens, 2014). Most

¹ Alternatively, the BF can be interpreted as an updating factor, from prior odds to posterior odds.

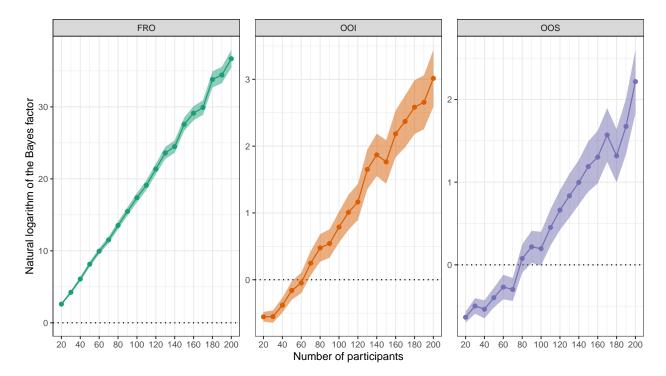

Figure 2. Average natural logarithm of the Bayes factor in favour of the alternative hypothesis, along with its standard error, computed over 1000 datasets of increasing size simulated from the posterior predictive distribution of the varying-intercept multivariate Bayesian regresion model. A log-BF belows 0 represents evidence for the null hypothesis (relative to the alternative) and a log-BF above 0 represents evidence for the alternative hypothesis (relative to the null).

importantly, an assumption of the present analysis is that the data from Moffatt et al. 154 (2020) is our best source of information regarding the main effect of interest (in addition to 155 the prior we specified earlier). However, the present analysis also differs from the 156 frequentist post-hoc power analysis on several grounds. First, with the present analysis, we do not aim to assess the ability of our statistical test to pass some dichotomic threshold 158 (e.g., accept/reject). Instead, we aim to assess how the BF₁₀ (i.e., the evidence for the 159 alternative hypothesis, relative to the null hypothesis) behaves with varying sample sizes. 160 Second, the present analysis relies on the posterior predictive distribution of the model 161 fitted on the data from Moffatt et al. (2020), which naturally incorporates uncertainty 162

about the effect of interest. By simulating datasets of varying sample sizes from the posterior predictive distribution (and by relying on a large number of simulations), uncertainty about the effect size is naturally incorporated into the simulation.

166 Manipulating rumination within-subject

167

168

169

170

171

In Nalborczyk, Banjac, et al. (2020), we manipulated the modality of rumination (whether it is verbal or non-verbal) in a between-subject manner to avoid order effects... In contrast to this approach, Moffatt et al. (2020) asked participants to ruminate and then distract themselves (or reciprocally), after an induced stressor (an induced failure)...

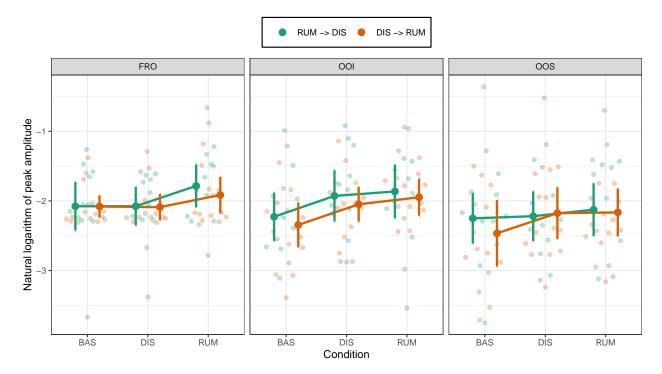

Figure 3. Average log-EMG amplitude by muscle and condition. The black dots and intervals represent the by-group average and 95% confidence interval (N=26). The horizontal white line in the violin plot represents the median. The grey dots represent the individual-level average natural logarithm of the EMG amplitude by muscle and condition.

About the order effects, Moffatt et al. (2020) say:

"Unless otherwise reported, the inclusion of order in which the conditions were
completed as a between-subjects variable as part of a mixed-design ANOVA
produced no significant main effects or interactions involving order."

Unfortunately, the same line of reasoning applies for testing the effect of the order,
which is even less powered than the test of the main effect of interest, rendering it
practically uninformative...

Does everyone?
